Abstract:
In this study we examined the levels of testosterone, triglycerides and cholesterol, before during, and after hibernation of the Desert Tortoise. The results revealed that testosterone reached high level after hibernation when compared with the level during hibernation. On the other hand, triglycerides and cholesterol reached high levels during hibernation.

Keywords:- Hibernation; triglycerides and cholesterol, testosterone, T.g. cyrenaica.
INTRODUCTION
Hibernation is a state of inactivity and metabolic depression in animals, characterized by lower body temperature, slower breathing, and/or lower metabolic rate. Hibernating animals conserve energy, especially during winter when food supplies are limited, tapping energy reserves, body fat, at a slow rate (Watts et al., 1981). Hibernation in endotherms and ectotherms is characterized by an energy-conserving metabolic depression due to low body temperatures and poorly understood temperature-independent mechanisms. Rates of gas exchange are correspondingly reduced. In hibernating mammals, ventilation falls even more than metabolic rate leading to a relative respiratory acidosis that may contribute to metabolic depression. Breathing in some mammals becomes episodic and in some small mammals significant apneic gas exchange may occur by passive diffusion via airways or skin. In ectothermic vertebrates, extrapulmonary gas exchange predominates and in reptiles and amphibians hibernating underwater accounts for all gas exchange. In aerated water, diffusive exchange permits amphibians and many species of turtles to remain fully aerobic, but hypoxic conditions can challenge many of these animals (Watts et al., 1981). Oxygen uptake into blood in both endotherms and ectotherms is enhanced by increased affinity of hemoglobin for O2 at low temperature. Regulation of gas exchange in hibernating mammals is predominately linked to CO2/pH, and in episodic breathers, control is principally directed at the duration of the apneic period (Milsom and Jackson, 2011). Control in submerged hibernating ectotherms is poorly understood, although skindiffusing capacity may increase under hypoxic conditions. In aerated water blood pH of frogs and turtles either adheres to alpha-stat regulation (pH ~8.0) or may even exhibit respiratory alkalosis. Arousal in hibernating mammals leads to restoration of euthermic temperature, metabolic rate, and gas exchange and occurs periodically even as ambient temperatures remain low, whereas body temperature, metabolic rate, and gas exchange of hibernating ectotherms are tightly linked to ambient temperature (Milsom and Jackson, 2011). This study aimed to study Changes in serum levels of testosterone, triglycerides and cholesterol, before during, and after hibernation of the Desert Tortoise, Testudograecacyrenaica.

MATERIAL AND METHODS
Experimental animals:
A total of forty adults, 20 male and 20 female of Desert Tortoise Testudograeca (T. g. Cyrenaica) were collected from Al jable Al Kder about 25 km², (Al-Blanj in south of Omer Almkhtar University - Al-Bayda city eastern Libya) during winter and summer season between 2016 and 2017 and used in the present study. Once caught, the animals were anesthetized with diethylether and blood was collected and centrifuged at 3000 g for 5 minutes and serum collected and kept in refrigerator at -80ºC.

Determination of serum triglycerides:
Principle:
Concentration of triglycerides was determined according to the method described by Fossati and Prencipe (1982), using biodiagnostic kit according to the following reactions:

\[
\text{Triglycerides} \rightarrow \text{Glycerol + fatty acids} \\
\text{Glycerol + ATP} \rightarrow \text{Glycerol-3-phosphate + ADP} \\
\text{Glycerol-3-phosphate oxidase} \rightarrow \text{Dihydroxyacetone phosphate + H}_2\text{O} \\
\text{Peroxidase} \rightarrow \text{Quinoneimine}
\]

Determination of serum total cholesterol:
Principle:
Total cholesterol was determined using biodiagnostic kit reagents and according to the method described by Allainet al. (1974), and the following reactions.

\[
\text{Cholesterol Esterase} \rightarrow \text{Cholesterol-ester + H}_2\text{O} \rightarrow \text{Cholesterol + Fatty acid} \\
\text{Cholesterol Oxidase} \rightarrow \text{Cholesterol + O}_2 \rightarrow \text{Cholestene-3-one+H}_2\text{O} \\
\text{Peroxidase} \rightarrow \text{2H}_2\text{O} + \text{phenol +4-Aminoantipyrine} \rightarrow \text{quinoneimine +4H}_2\text{O}
\]

RESULTS:
Order Chelonia (Testudines) or turtles: Desert Tortoise divided into two species in Libya Testudograeca (T.g.Cyrenaica) and Egyptian Tortoise.
Testudokleinmanni (marwa, 2017)

*T. g. Cyrenaica* species distributing in Cyrenaica in eastern Libya specially in AlJabal al Akhdar, Tubruk, Al-marj and AL-tmemy, while the range and the status of the Egyptian tortoise *Testudokleinmanni* in Libya are poorly known due to the country’s political isolation. Once contiguous with Egyptian populations, now virtually extinct, the species ranges continuously from the eastern border nearly to Tripoli in the west. Contrary to previous indications, *T. kleinmanni* is absent from the tableland of the Jabal al Akhder and from its northern and western coastal foothills. On the other hand, it is widespread along the coastal area of the Gulf of Sirte, continuing into Tripolitania along the coast to the vicinity of Tripoli. Evidence for the presence of *T. kleinmanni* in the JabalNafusa Range south of there does not exist (Christoph Schneider and Willi Schneider 2008).

**The relationship between hibernation and serum triglycerides:**

Tables (1) and figure (1) illustrates the levels of serum triglyceride in both male and female of the adult tortoise (*T. g. Cyrenaica*) during activity season (summer season) and hibernation season (winter season). The assayed the levels of serum triglyceride of both sex were markedly decreased during activity season (summer season) while, the levels of serum triglyceride in both sex were increased in hibernation season (winter season). There was wide variations of the serum triglyceride between males and females during hibernation season.

**Table (1).** Shows changes of the levels of serum triglyceride of the adult tortoise (*T. g. Cyrenaica*) during hibernation season (winter season) and activity season (summer season) (Mean±SE).

The relationship between hibernation and testosterone hormone (T):

Tables (3) and figure (3) illustrates the levels of testosterone hormone (T) in male of the adult tortoise (*T. g. Cyrenaica*) during activity season (summer season) and hibernation season (winter season). The assayed the levels of testosterone hormone (T) in the male were markedly increased during activity season (summer season). on the other hand, the levels of testosterone hormone (T) in the male were decreased in hibernation season (winter season).

**DISCUSSION:**

The ecology and physiology of *T. g. Cyrenaica* (Linnaeus 1758) in North Africa especially in Libya is still little studied, although the amount of information on the subject has increased considerably within the last ten years. This lack of
knowledge hampers understanding of how ecological and physiological differences may arise as a result of the environment change in terms of seasonal variation.

The desert Tortoise is a member of the reptile family that is composed of snakes, lizards, crocodiles and other chelonians (turtles). Turtles are obviously different from other reptiles by the shell or box that completely covers the body. The shell is actually a part of the body and hardens about three years after hatching (Muro et al., 1998).

Desert Tortoise, often known as Testudinidae, is a medium-sized Tortoise occurring in desert habitats distributed in the Mediterranean. The division of spurted-twig tortoises into subspecies is difficult and confusing. Given the huge range over three continents, the various terrains, climates, and biotopes have produced a huge number of varieties, with new subspecies constantly being discovered. Currently, at least 20 subspecies are published, as following: T. g. graeca (North Africa and South Spain), T. g. soussensis (South Morocco), T. g. marokkensis (North Morocco), T. g. nabeulensis (Tunisian spur-twig tortoise (Tunisia)), T. g. cyrenaica (Libya), T. g. iberica (Turkey), T. g. armeniaca - Armenian tortoise (Armenia), T. g. buxtoni (Caspian Sea), T. g. terrestris (Israel/Lebanon), T. g. zarudnyi (Iran/Azerbaijan) and T. g. whitei (Algeria) (Marwa, 2017).

Hibernation is a very intricate and sensitive biological event for the reptilian species and entails different physiological mechanisms. Specific brain regions also remain active during deep torpor (Heller, 1979), whereas the hibernator’s brain temperature can drop close to the freezing point of water and the brain becomes electrically quiescent to surface electroencephalography (Heller & Ruby, 2004). In fact, as a hibernator enters into deep torpor, the cortex falls ‘asleep’, which may be, via c-fos expression, a result of the activation of the reticular thalamic nucleus that suppresses arousal activity (Bratincsak et al., 2007). During hibernation, the ‘biological clock’ is working; the profound activity of the choroidplexus, the ependymal cells of the lateral ventricles and third ventricles suggests that the production of the cerebrospinal fluid or some unrecognized function of these cells might be an important factor in maintaining torpor (Bratincsak et al., 2007).

Hibernation in reptiles is an evolutionary adaptation to harsh environmental conditions, such as cold weather and starvation. The decrease in body temperature is associated with profound reductions of blood flow, oxygen delivery (Ferriechs et al., 1994), and glucose utilization (Ferriechs et al., 1995) in body organs and in particular the brain. Hibernation represents a condition of metabolic depression, where homeostasis is maintained with minimal biological activities. Several regulations need to be made to support hibernation. According to Wade (1997), testosterone can stimulate both masculine courtship and copulatory behaviors, and estrogen and testosterone facilitate feminine receptivity. These results suggest roles for both aromatase (which catalyzes the conversion of testosterone to estradiol) and 5α-reductase (which converts testosterone to dihydrotestosterone). This study documents the presence of both enzymes in the brain of the green anole and indicates that the activity of 5α-reductase is much higher than that of aromatase in whole brain homogenates. However, differences exist among brain regions, such that aromatase activity is higher in preoptic area/hypothalamic dissections, whereas 5α-reductase is much more active in the brain stem.

Derickson (1974) suggested that, the close correlation between wet fat body mass and total lipid mass in Agama stellioestello may be useful in predicting total lipid mass available at different times of year by measuring wet fat body mass only, thus not destroying the remaining tissues. Tied lipid cycles to life history patterns by considering food availability as a determinant factor. As he stated, low food availability would result in a longer time span for the animal to reach reproductive size and lower quantities of stored lipids. Smaller quantities of lipids can result in lower reproductive effort, which can result in longer life span. Agama stellioestello fits within this category, since it matures in its second year of life (Loumbourdis, unpublished) and stores a low percentage of lipids. Although there are no quantitative data, the environment in which Agama stellioestello lives could not be considered rich in resources, thus resulting in low lipid levels.

Unlike to Derickson (1974). In Agama stellioestello, all the lipid depots decline during hibernation, but the most prominent one is that of fat bodies. A calculation based on the absolute values of lipids consumed during hibernation showed that females lost 190 mg from the carcass and 370 mg from the fat bodies. Taking into account that their mean wet weight was 45 g, it was estimated that 4e-males consumed lipids equivalent to 1.24% of their total wet weight. Similar calculations for males showed that they consumed 720 mg of lipids which are equivalent to 1.26% of their total weight. (Selcer 1987). Reported that, Fat bodies and liver masses in lizards store energy for use during times of high energetic demand such as the breeding season.

Ramirez-Bautista (1995). Also mention that, Amphibians and reptiles “have within the peritoneal cavity pairs of solid fat bodiess either anchored to the kidneys or near the rectum. These are important resource storehouses needed for foribheration and breeding.

DeMarco and Guillette (1992). Suggested that, Although the liver of reptiles serves an immunological role, another major function is glucose metabolism, the liver removes surplus glucose from the blood and stores it as glycogen and reptiles adopt feeding strategies that store energy within these structures in the most efficient manner. Similar findings were reported by (Abdalahafid, 2013) whereby observed that, in the liver of U. acanthinura, Genomic DNA showed apparent separation during hibernation. Also, caspase3 and caspase9 activity reached a high level in the liver tissue during hibernation comparing with activity season. In addition, Hibernation in reptiles is an evolutionary adaptation to harsh environmental conditions, such as cold weather and starvation. The decrease in body temperature is associated with profound reductions of blood flow, oxygen delivery, and glucose utilization, in body organs and in particular the brain and liver. Hepatic cells and structures during hibernation reflected the reduced metabolic activity of U. acanthinura. In addition, these changes illustrated the drastic edematous lesions and damage of the natural cells especially hepatic cells in liver.
